BACKGROUND: Few studies have investigated traffic-related air pollution as a risk factor for respiratory infections during early childhood.

OBJECTIVES: We aimed to investigate the association between air pollution and pneumonia, croup, and otitis media in 10 European birth cohorts—BAMSE (Sweden), GASPII (Italy), GINIplus and LISAPlus (Germany), MAAS (United Kingdom), PIAMA (the Netherlands), and four INMA cohorts (Spain)—and to derive combined effect estimates using meta-analysis.

METHODS: Parent report of physician-diagnosed pneumonia, otitis media, and croup during early childhood were assessed in relation to annual average pollutant levels [nitrogen dioxide (NO₂), nitrogen oxide (NO_x), particulate matter ≤ 2.5 μm (PM_{2.5}), PM_{2.5} absorbance, PM₁₀, PM_{2.5-10} (coarse PM)], which were estimated using land use regression models and assigned to children based on their residential address at birth. Identical protocols were used to develop regression models for each study area as part of the ESCAPE project. Logistic regression was used to calculate adjusted effect estimates for each study, and random-effects meta-analysis was used to calculate combined estimates.

RESULTS: For pneumonia, combined adjusted odds ratios (ORs) were elevated and statistically significant for all pollutants except PM_{2.5} (e.g., OR = 1.30; 95% CI: 1.02, 1.65 per 10-μg/m³ increase in NO₂ and OR = 1.76; 95% CI: 1.00, 3.09 per 10-μg/m³ PM₁₀). For otitis media and croup, results were generally null across all analyses except for NO₂ and otitis media (OR = 1.09; 95% CI: 1.02, 1.16 per 10-μg/m³).

CONCLUSION: Our meta-analysis of 10 European birth cohorts within the ESCAPE project found consistent evidence for an association between air pollution and pneumonia in early childhood, and some evidence for an association with otitis media.

Air pollution and respiratory infections during early childhood: an analysis of 10 European birth cohorts within the ESCAPE project. *Environ Health Perspect* 122:107–113; <http://dx.doi.org/10.1289/ehp.1306755>

Introduction

Respiratory infections are a leading reason for outpatient physician visits and hospitalizations among children (Williams et al. 2002). Most infections resolve with minimal use of health care resources; however, episodes of severe or recurrent infection may require hospitalization or surgery, and the resultant burden on resources is substantial (Black et al. 2010).

Young children are particularly susceptible to respiratory pathogens and also to air pollution (Bateson and Schwartz 2008;

Heinrich and Slama 2007). There is strong evidence that indoor air pollution, such as secondhand smoke and the use of biomass, is a risk factor for respiratory infections in children (da Costa et al. 2004). Evidence is growing to support an association with outdoor air pollution as well (Brauer et al. 2006; Leonardi et al. 2000; MacIntyre et al. 2011).

The European Study of Cohorts for Air Pollution Effects (ESCAPE 2009) is a project aimed at investigating the impacts of long-term exposure to air pollution through the development of harmonized exposure

data assigned to previously established cohorts that have collected information on specific health outcomes of interest for air pollution research. We analyzed data from

The research leading to these results was funded by the European Community's Seventh Framework Program (FP7/2007–2011) under grant 211250. The BAMSE study was supported by the Swedish Research Council FORMAS (for Environment, Agricultural Sciences and Spatial Planning), the Stockholm County Council, the Swedish Foundation for Health Care Sciences and Allergy Research, and the Swedish Environmental Protection Agency. The GINIplus study was supported for the first 3 years by the Federal Ministry for Education, Science, Research and Technology, Germany (interventional arm) and Helmholtz Zentrum München, Germany (former GSF; National Research Center for Environment and Health) (observational arm). The LISAPlus study was supported by grants from the Federal Ministry for Education, Science, Research and Technology, Germany; Helmholtz Zentrum München, Germany (former GSF); Helmholtz Centre for Environmental Research—UFZ, Germany; Marien-Hospital Wesel, Germany; and Pediatric Practice, Bad Honnef, Germany. The PIAMA study is supported by The Netherlands Organization for Health Research and Development; The Netherlands Organization for Scientific Research; The Netherlands Asthma Fund; The Netherlands Ministry of Spatial Planning, Housing, and the Environment; and The Netherlands Ministry of Health, Welfare, and Sport. MAAS was supported by an Asthma UK Grant (04/014); the JP Moulton Charitable Foundation, UK; and the James Trust and Medical Research Council, UK (G0601361). INMA was funded by grants from the Spanish Ministry of Health-Instituto de Salud Carlos III (Red INMA G03/176, CB06/02/0041, FISPI041436, FIS-PI081151, FIS-PI042018, FIS-PI09/02311, FIS-PI06/0867, FIS-PS09/00090, FIS-FEDER 03/1615, 04/1509, 04/1112, 04/1931, 05/1079, 05/1052, 06/1213, 07/0314, and 09/02647); Generalitat de Catalunya-CIRIT, Spain (1999SGR 00241); Conselleria de Sanitat Generalitat Valenciana, Spain; Universidad de Oviedo, Obra social Cajastur, Spain; Department of Health of the Basque Government, Spain (2005111093 and 2009111069); Provincial Government of Gipuzkoa (DFG06/004 and DFG08/001), Spain; and Fundación Roger Torné, Spain. GASPII was funded by The Italian Ministry of Health (ex art.12 D.Lgs 502/92, 2001).

10 European birth cohorts and completed a meta-analysis of air pollution and respiratory infection (pneumonia, croup, and otitis media) during early childhood.

Methods

Study population. We included 10 ESCAPE birth cohorts. The inclusion criteria for each birth cohort were that data on at least one outcome of interest were available during early childhood, and that the ESCAPE exposure assignment was complete.

BAMSE (Children, Allergy, Milieu, Stockholm, Epidemiological Survey) is a population-based prospective birth cohort of children born during 1994–1996 in Stockholm County, Sweden (Wickman et al. 2002). GASPII (Gene and Environment: Prospective Study on Infancy in Italy) is a prospective birth cohort of children born during 2003–2004 in Rome, Italy (Porta et al. 2007). GINIplus (German Infant Nutrition Intervention Study Plus environmental and genetic influences on allergy development) is a population-based prospective birth cohort, with a nutritional intervention, of children born during 1995–1998 in Wesel and Munich, Germany (Zirngibl et al. 2002). LISApplus (Influence of Life-style Factors on the Development of the Immune System and Allergies in Childhood Plus the influence of traffic emissions and genetics) is a population-based prospective birth cohort study of children born during 1997–1999 in Wesel, Munich, Leipzig, and Bad Honnef, Germany (Heinrich et al. 2002). INMA (Infancia y Medio Ambiente; Environment and Childhood) is a network of Spanish birth cohorts. The four INMA cohorts in the present analysis comprise children born during 2004–2008 in both major cities and rural towns—Asturias, Gipuzkoa, Sabadell, and Valencia (Guxens et al. 2012). MAAS (Manchester Asthma and Allergy Study) is an unselected, prospective population-based birth cohort study (with a small nested allergen control intervention) of children born during 1995–1997 in the Greater Manchester conurbation in the United Kingdom (Custovic et al. 2002). Finally, the PIAMA (Prevention and Incidence of Asthma and Mite Allergy) study is a population based prospective birth cohort, with an intervention component, of children born during 1996–1997 in cities and small towns across the Netherlands (Brunekreef et al. 2002). Each cohort obtained parental consent and protocols were approved by all relevant ethical review boards.

Exposure to outdoor air pollution was estimated using land use regression (LUR) models, and methods were harmonized across each cohort (Beelen et al. 2013; Cyrus et al. 2012; Eeftens et al. 2012a, 2012b; ESCAPE 2013). Briefly, sampling sites for particulate

matter ($n = 20$ – 40) and nitrogen oxides ($n = 40$ – 80) were strategically chosen for each study area to represent the spatial distribution of concentrations at the residential address of each child at birth, with some overrepresentation of locations with heavy traffic where the largest heterogeneity was expected. Three 2-week sampling campaigns were spread out over 1 year and used to estimate an annual average. Measurement data used to develop the LUR models were collected during 2008–2009 (BAMSE, GINIplus/LISApplus, PIAMA), 2009 (INMA), 2009–2010 (MAAS), and 2010–2011 (GASPII). The annual average was temporally adjusted using continuous measurement data from a fixed monitor that was used to capture background levels in each study area. Models based on GIS (geographic information system) variables related to traffic, land use, population density, altitude, and regional background pollution were developed using common ESCAPE protocols to predict measured air pollution concentrations.

Separate models were developed for nitrogen dioxide (NO_2), nitrogen oxides [NO_x ($\text{NO}_2 + \text{NO}$)], $\text{PM}_{2.5}$ (particulate matter $\leq 2.5 \mu\text{m}$ in diameter), $\text{PM}_{2.5}$ absorbance, PM_{10} ($\leq 10 \mu\text{m}$ in diameter), and coarse PM (PM_{10} – $\text{PM}_{2.5}$). In addition, two variables were created to describe traffic intensity at the residential address: traffic intensity on the nearest street, and traffic load on all major roads within a 100-m buffer. Annual average air pollution concentrations and traffic intensity variables were assigned to children for the first year of life based on their residential address reported at birth. The LISApplus study centers of Leipzig and Bad Honnef were not included in the ESCAPE exposure assessment, so children from these cities could not be included in the meta-analysis.

The air pollution data used to derive the ESCAPE exposure models were measured in 2008–2011, whereas children included in the study cohorts were born as early as 1994. Therefore, we conducted sensitivity analyses using routine monitoring data to back-extrapolate exposure estimates based on LUR to each child's year of birth. We used two approaches for the back-extrapolation: The first used the ratio of the average concentration measured from the date of birth through the second birthday to the average concentration measured during the ESCAPE monitoring year; the second used the absolute difference between the average concentrations at each time period (ESCAPE 2013). Both methods altered the spatial contrast derived from the current LUR models without affecting the spatial patterns of air pollutants in the study areas.

For each cohort, parents reported (yes/no) physician-diagnosed pneumonia, otitis media, and croup during early childhood (see

Supplemental Material, p. 2, for the specific questions used for each cohort). Outcomes were assessed at 6 months (GASPII, LISApplus), 1 year (BAMSE, GINIplus, INMA Valencia, LISApplus, PIAMA), 14 months (INMA Gipuzkoa, INMA Sabadell), 15 months (GASPII), 18 months (LISApplus, INMA Asturias), 2 years (BAMSE, GINIplus, LISApplus, PIAMA), and 3 years (MAAS). It was not possible to evaluate respiratory infections restricted to the first 2 years of life for the MAAS birth cohort because these outcomes were not assessed in the full cohort until 3 years of age. Pneumonia data were available for all cohorts; otitis media data were available for all except GINIplus and MAAS; and croup data were available for all except GASPII, the four INMA cohorts, and PIAMA. Cumulative incidence was modeled in each analysis, unless otherwise specified.

We used logistic binomial regression in all individual cohort analyses, and statistical significance was defined by p -values < 0.05 . Air pollution was entered as a continuous variable and was not transformed. Models were assessed using the Hosmer–Lemeshow goodness-of-fit test and the Pearson's chi-square test. Potential confounders were identified from previous literature and selected *a priori*. Individual cohort models were adjusted for municipality/city (BAMSE only), sex, older siblings (any/none), partial or exclusive breastfeeding at 6 months, atopy of either parent, child-care attendance reported at any time during follow-up, maternal smoking during pregnancy, secondhand smoke in the home reported at any time during follow-up (not available for INMA), visible mold or dampness in the home, use of gas stove, birth season (winter: January–March; spring: April–June; summer: July–September; fall: October–December), parental socioeconomic status [highest education attained by either parent (BAMSE, GINIplus, LISApplus, PIAMA, INMA: low, medium, high); highest occupational level by either parent (GASPII: low, medium, high); or household income (MAAS: $< \text{€}10,000$; $\text{€}10,000$ – $20,000$; $\text{€}20,000$ – $30,000$; $> \text{€}30,000$)], and intervention (GINIplus, MAAS, and PIAMA only). Models for traffic intensity and traffic load were additionally adjusted for background NO_2 concentrations. Children with missing data for any covariate were excluded from individual analyses. Based on the ESCAPE protocol, we calculated estimates for the following increments in exposure: $10 \mu\text{g}/\text{m}^3$ for NO_2 , $20 \mu\text{g}/\text{m}^3$ for NO_x , 1 unit for $\text{PM}_{2.5}$ absorbance, $5 \mu\text{g}/\text{m}^3$ for $\text{PM}_{2.5}$, $10 \mu\text{g}/\text{m}^3$ for PM_{10} , $5 \mu\text{g}/\text{m}^3$ for coarse PM, 5,000 vehicles/day for traffic intensity on the nearest street; and 4,000 vehicle-km/day for traffic load on major roads within a 100-m buffer. We assessed heterogeneity of effect estimates

between studies using the I^2 statistic (Huedo-Medina et al. 2006). We used random-effects meta-analysis models to calculate combined estimates (DerSimonian and Laird 1986).

We used sensitivity analyses to test the robustness of effect estimates to the inclusion of additional potential confounders: birth weight, maternal age at birth, and area-level socioeconomic indicators. In addition, we stratified associations for outcomes that were diagnosed during the first year of life and outcomes diagnosed during the second year of life for cohorts that completed follow-ups at 1 and 2 years of age (BAMSE, GINIplus, LISApplus, PIAMA). Additional analyses were stratified by sex, parental socioeconomic status (low, middle, or high), and residential mobility (moved from the birth address at any time during the follow-up period) to examine potential effect modification. As noted above, we also performed sensitivity analyses using exposure estimates that were recalculated for selected pollutants using back-extrapolation techniques to assess the consistency of associations. In addition, we performed a sensitivity analysis of the influence of neighborhood clustering by including an area-level variable (BAMSE: neighborhood; GINIplus: ZIP code; LISApplus: ZIP code; INMA: rural indicator; PIAMA: neighborhood) as a random effect in adjusted models. Area-level data were not available for GASPII or MAAS. Finally, we used two-pollutant models to estimate the independent effects of NO₂ and PM.

All individual and combined analyses were completed using identical protocols. Individual estimates are presented by cohort except for the German birth cohorts (LISApplus and GINIplus), which had

almost identical study designs and parental questionnaires, and are presented as GINI/LISA North (Wesel) and GINI/LISA South (Munich) because separate air pollution models were developed for each area as part of ESCAPE. Statistical analyses were completed using SPSS version 20 (IBM SPSS, Armonk, NY, USA) and SAS version 9.1 (SAS Institute Inc., Cary NC, USA).

Results

There was complete outcome (at least one), exposure (a minimum of NO₂ and NO_x) and potential confounder information for 16,059 children across all 10 cohorts (79.6% of the total recruited population). Children excluded due to missing data were more likely to have parents of lower socioeconomic status (BAMSE, GINI/LISA South, GINI/LISA North, MAAS, PIAMA), mothers who smoked during pregnancy (BAMSE, GASPII, GINI/LISA South, GINI/LISA North, PIAMA); and were less likely to be breastfed for at least 6 months (GASPII, GINI/LISA South, GINI/LISA North, MAAS, PIAMA) or to have atopic parents (GINI/LISA South, INMA Sabadell). Table 1 shows the cumulative incidence of parent-reported physician-diagnosed respiratory infection, by cohort. The cumulative incidence of pneumonia during early childhood ranged from 1.5% in INMA Sabadell to 7.9% in BAMSE (0.7–3.6% during the first year only). Otitis media ranged from 21.8% in GASPII to 50.0% in BAMSE (6.8–26.6% for the first year), and croup ranged from 10.6% in MAAS to 12.9% in GINI/LISA North (4.2–5.6% for the first year). There were differences in breastfeeding, child-care attendance, parental atopy, and secondhand smoke exposure

among the cohorts (see Supplemental Material, Table S1). Air pollution concentrations were highest in GASPII and lowest in BAMSE; GINI/LISA South, GINI/LISA North and PIAMA had similar mean concentrations (Table 1). Additional statistics on air pollutant concentrations by cohort are available in Supplemental Material, Table S2. Air pollutant concentrations were moderately to highly correlated (see Supplemental Material, Table S3; e.g., correlation between PM_{2.5} and NO₂ ranged between 0.42 and 0.80, and correlations between PM_{2.5} absorbance and NO₂ ranged between 0.40 and 0.93).

Associations between air pollution and respiratory infection during early childhood are presented in Figure 1 for *a*) individual and *b*) combined effect estimates. Table 2 presents combined effect estimates for crude (adjusted for sex and municipality) and adjusted (adjusted for all potential confounders) models and *p*-values for heterogeneity. The heterogeneity between studies varied and the largest I^2 statistics were for models of pneumonia and NO₂, PM_{2.5}, and PM₁₀. Effect estimates were robust to adjustment for older siblings, breastfeeding, parental atopy, child care, maternal smoking during pregnancy, environmental tobacco smoke, visible mold or dampness, use of gas stove, birth season, and parental socioeconomic status. For pneumonia, elevated odds ratios (ORs) were found in almost all analyses, and the combined estimates were statistically significant for all measures of air pollution except PM_{2.5} (OR = 2.58; 95% CI: 0.91, 7.27 for a 5- $\mu\text{g}/\text{m}^3$ increase). For otitis media and croup, results were generally null across all analyses except for NO₂ and otitis media, for which the adjusted OR was 1.09 (95% CI: 1.02, 1.16 for a 10- $\mu\text{g}/\text{m}^3$ increase).

Table 1. The cumulative incidence of respiratory infections and distribution of air pollution for each ESCAPE birth cohort.

IQR, interquartile range.

^aAssessed at 6 months. ^bAssessed at 12 months. ^cAssessed at 15 months. ^dAssessed at 18 months. ^eAssessed at 14 months. ^fAssessed at 3 years. ^gRequiring antibiotic. ^hOtitis media was collected only in the LISApplus study (total South *n* = 1,242; North *n* = 280).

Effect estimates in two-pollutant models that included NO₂ plus one of the PM exposures were closer to the null (vs. estimates from single-pollutant models), and the only statistically significant finding was for NO₂ and otitis media (OR = 1.13; 95% CI: 1.01, 1.26 for a 10-µg/m³ increase in NO₂) when adjusted for coarse PM (see Supplemental Material, Table S4). Confidence intervals increased substantially in two-pollutant models, reflecting the high correlation between pollutants (see Supplemental Material, Table S3).

All measures of air pollution were associated with pneumonia (*p* < 0.05) in analyses restricted to the first year of life (e.g., OR = 4.06; 95% CI: 1.93, 8.57 for a 5-µg/m³ increase in PM_{2.5}) (Table 3).

Further, the combined effect estimate for all associations (pneumonia, otitis media, and croup) increased when analyses were restricted to outcomes in the first year of life.

Stratified meta-analyses suggested slightly stronger effects in females and in those from middle socioeconomic groups (see Supplemental Material, Tables S5 and S6). In analyses stratified by residential mobility during follow-up, the associations between air pollution and respiratory infection were not consistent by strata: Pneumonia effects were greater for movers (OR = 1.62; 95% CI: 1.20, 2.18 vs. 1.21; 95% CI: 0.88, 1.67 for NO₂), whereas otitis media effects were greater for nonmovers (OR = 1.08; 95% CI: 1.01, 1.16 vs. 1.03; 95% CI: 0.71, 1.48 for NO₂; see Supplemental Material, Table S7).

Inclusion of additional covariates into the individual cohort models (birth weight, maternal age and area level socioeconomic indicators) did not change air pollution effect estimates or improve model fit (data not shown). There was no consistent evidence for spatial clustering when area-level variables were included as a random effect in models (data not shown). Finally, analyses using back-extrapolated monitoring data were generally consistent with the main findings (see Supplemental Material, Table S8).

Discussion

As part of the ESCAPE project we had the unprecedented opportunity to examine outdoor air pollution as a risk factor for respiratory infection during early childhood in

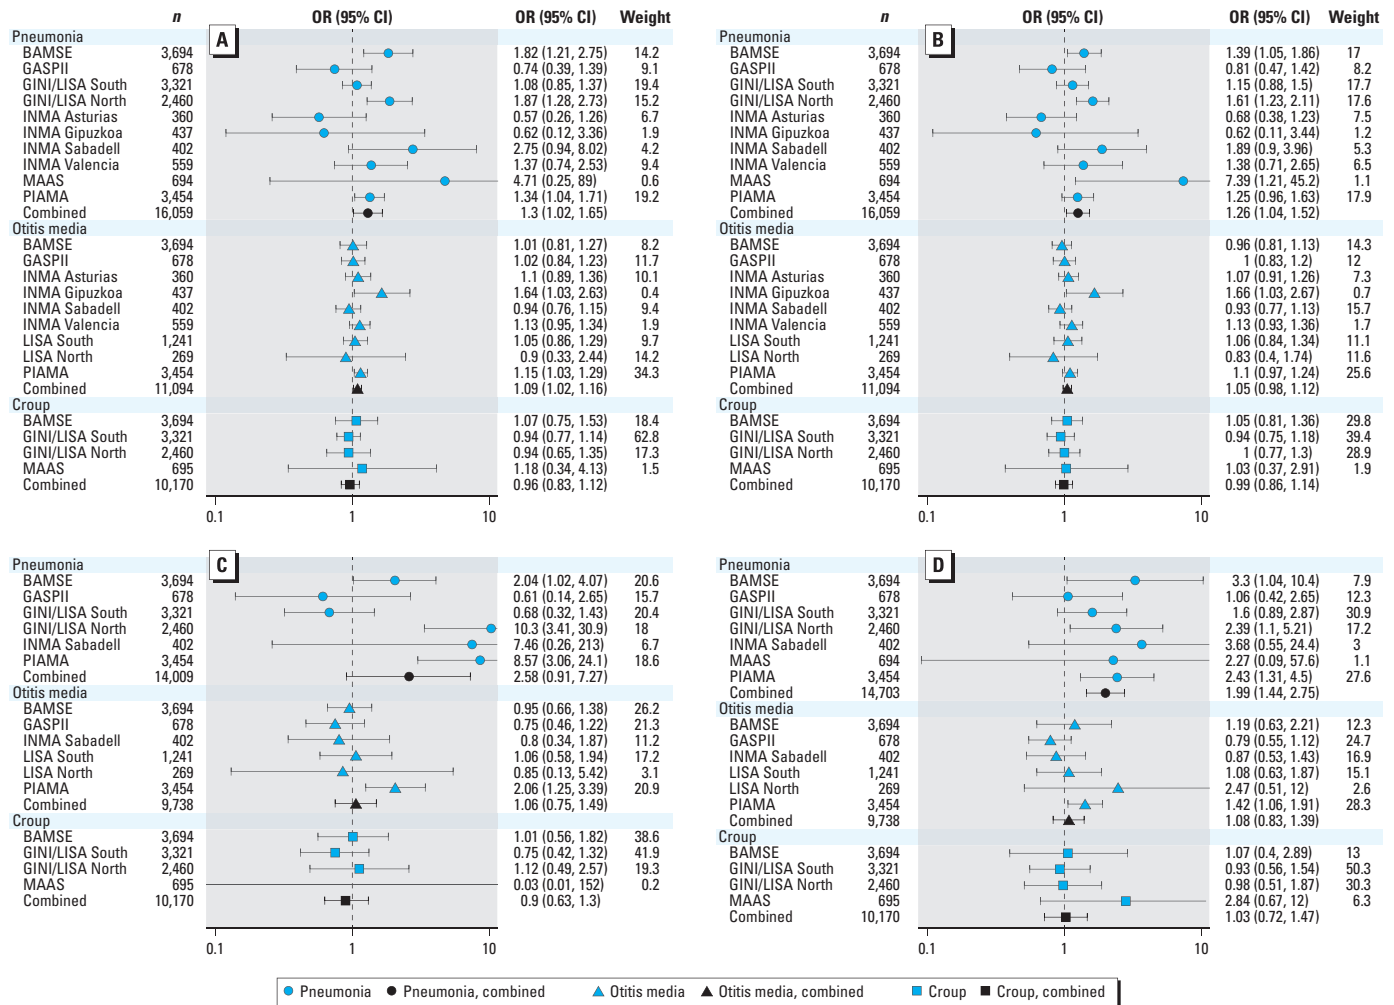

Figure 1. Forest plots of individual cohort and combined effect estimates (ORs) by outcome for (A) NO₂, (B) NO_x, (C) PM_{2.5}, (D) PM_{2.5} absorbance, (E) PM₁₀, (F) coarse PM, (G) traffic intensity on nearest street, and (H) traffic load on all major roads. Weight indicates relative weight (%) assigned using random-effects meta-analysis. The lifetime cumulative incidence of respiratory infection (pneumonia, otitis media, croup) was assessed at 12 months (INMA Valencia), 14 months (INMA Gipuzkoa, INMA Sabadell), 15 months (GASPII), 18 months (INMA Asturias), 24 months (BAMSE, GINI/LISA North, GINI/LISA South, PIAMA), and 36 months (MAAS) of age. Individual cohort models were adjusted for municipality (BAMSE), sex, older siblings, breastfeeding at 6 months, atopy of either parent, any child-care reported during follow-up, maternal smoking during pregnancy, any environmental tobacco smoke in the child's home reported during follow-up, visible mold or dampness in the home, use of gas stove, birth season, parental socioeconomic status (low, medium, high), and intervention (GINIplus, MAAS, PIAMA). Associations are presented for the following increments in exposure: 10 µg/m³ for NO₂, 20 µg/m³ for NO_x, 5 µg/m³ for PM_{2.5}, 1 unit for PM_{2.5} absorbance, 10 µg/m³ for PM₁₀, 5 µg/m³ for coarse PM, 5,000 vehicles/day for traffic intensity on the nearest street; and 4,000 vehicle-km/day for traffic load on major roads within a 100-m buffer.

an analysis combining 10 European birth cohorts ($N_{\text{Total}} = 16,059$) with data on parent-reported physician-diagnosed pneumonia, otitis media, and croup; we also examined individual air pollution exposure estimates based on common ESCAPE protocols. We found consistent evidence for an association between air pollution and pneumonia, and some evidence for otitis media, during the first two years of life.

Urban air pollution has been associated with respiratory tract infections (Jedrychowski et al. 2013; Lin et al. 2005), pneumonia (Gouveia and Fletcher 2000), croup (Schwartz et al. 1991), persistent cough (Esplugues et al. 2011), and otitis media (MacIntyre et al. 2011) during childhood. Associations have also been reported for indoor air pollution and pneumonia in developing countries (da Costa et al. 2004; Mahalanabis et al. 2002) where concentrations are considerably higher than in our study areas. Our findings are consistent with previous studies that used similar methods to examine air pollution and otitis media in three of our cohorts—PIAMA (Brauer et al. 2006), LISApplus Munich (Brauer et al. 2006), and INMA (Aguilera et al. 2013)—and a recent meta-analysis on long-term $\text{PM}_{2.5}$ and acute lower respiratory infection in children, which also included the PIAMA study (Mehta et al. 2013).

Similar to secondhand smoke (U.S. Department of Health and Human Services 2006), air pollution is thought to increase susceptibility to respiratory infections primarily via an inflammatory response (Li et al. 2008). Urban air pollution may impair defense mechanisms (Clarke et al. 2000; Leonardi et al. 2000), and oxidant pollutants, in particular, may exacerbate virus-induced inflammation of the respiratory system (Lambert et al. 2003; Spannhake et al. 2002).

Analyses were restricted to the first years of life to include the period of greatest age-specific incidence of respiratory infections (Schnabel et al. 2009; Walker et al. 2013). Our findings suggested that air pollution effects may be slightly stronger during the first year (Table 3). This finding could highlight a unique period of susceptibility when children are at increased risk of respiratory infections due to air pollution (Gehring et al. 2002; Gouveia and Fletcher 2000; Heinrich and Slama 2007). It is also possible that the null findings for infections during the second year of life are due to increased exposure misclassification as older children may spend less time at their home address due to increased child-care enrollment.

A unique strength of LUR models is their ability to capture small-scale spatial variability in exposure; however, the measurements

used to create the ESCAPE exposure models were taken after the birth year (Eeftens et al. 2012a; Cyrus et al. 2012), and this may have introduced exposure misclassification. Although it is possible that overall levels of air pollution changed during this period, previous findings suggest that the spatial distribution of air pollutants within each area remained consistent (Cesaroni et al. 2012; Eeftens et al. 2011; Wang et al. 2013). Further, our sensitivity analyses using monitoring data to back-extrapolate exposure estimates to the actual first year of life were consistent with our main findings (see Supplemental Material, Table S8).

The wording of parental questionnaires was similar across each cohort, and previous research has shown good agreement between maternal recall and medical records during early childhood (D'Souza-Vazirani et al. 2005; Vernacchio et al. 2007). Geographic differences in the prevalence of outcomes across the cohorts were most pronounced for otitis media and may point to potential diagnostic biases or disease misclassification between countries. It was not possible to adjust for epidemics, the impact of vaccinations, or the frequency of infections because data were not available across all cohorts. Furthermore, defining upper respiratory tract infections (otitis media, croup) by physician

Figure 1. Continued.

Associations are presented for the following increments in exposure: 10 µg/m³ for NO₂, 20 µg/m³ for NO_x, 5 µg/m³ for PM_{2.5}, 1 unit for PM_{2.5} absorbance, 10 µg/m³ for PM₁₀, 5 µg/m³ for coarse PM, 5,000 vehicles/day for traffic intensity on the nearest street; and 4,000 vehicle-km/day for traffic load on major roads within a 100-m buffer; associations with traffic intensity and traffic load were additionally adjusted for background NO₂ concentrations.

^aBased on four studies: BAMSE, GINI/LISA North, GINI/LISA South, PIAMA. ^bBased on 3 studies: BAMSE, LISAPLUS North, LISAPLUS South, PIAMA. ^cBased on three studies: BAMSE, GINI/LISA North, GINI/LISA South. ^dDefined as 0–12 months. ^eDefined as 13–24 months. Models were adjusted for municipality (BAMSE), sex, older siblings, breastfeeding at 6 months, atopy of either parent, any child-care reported during follow-up, maternal smoking during pregnancy, any environmental tobacco smoke in the child's home reported during follow-up, visible mold or dampness in the home, use of gas stove, birth season, parental socioeconomic status (low, medium, high), and intervention (GINIplus, PIAMA). *p < 0.05.

diagnosis is complicated by the fact that not all infections present with acute symptoms severe enough to warrant a physician visit, in contrast with pneumonia, which routinely presents with a high fever and/or difficulty breathing (Edmond et al. 2012).

Conclusion

Our meta-analysis of 10 European birth cohorts found consistent evidence for an association between traffic-related air pollution and pneumonia, and some evidence to suggest an association with otitis media. Policies aimed at reducing air pollution may be successful in reducing the overall burden of pneumonia in early childhood.

CORRECTION

The value for “Traffic load on major streets within 100-m buffer” for GINI/LISA South in Table 1 was incorrect in the manuscript originally published online. It has been corrected here.
